555 Timer Mini-Project Lab Report

Pradyunn Vikram Kale

April 7, 2026

1 Introduction

The 555 Timer was originally designed in 1971 by Hans Camenzind, a swiss electronics engineer employed by Signetics in California. He spent months getting the 555 Timer to its final design. The 555 timer is simple to use, and reliable in a wide array of applications. For all of its applications, it is used in one of 3 modes. Monostable, astable, and bistable mode. With these modes, we can make circuits like PWM motor controllers, security alarms, audio generators etc. The objective of this project is to learn how 555 timers work and to build something cool out of them. I am interested in building a PWM generator using the 555 timers, as this connects to motor control, something I will be using a lot within GNC.

2 Theory

Figure 1: 555 Timer Internal Schematic

The main components inside the 555 timer are 2 comparators and an SR flip flop in cooperation with a voltage divider. In short, the 555 timer works by using a voltage divider and setting the voltage of specific nodes. For example, when looking at the diagram, the node after the first resistor from ground is $\frac{1}{3}V_{cc}$, and then the node after the 2nd resistor from ground is $\frac{2}{3}V_{cc}$. The lower comparator uses $\frac{1}{3}V_{cc}$ as a reference, when the trigger voltage falls below $\frac{1}{3}V_{cc}$, the comparator will output HIGH. This then asserts SET on the flip flop, which then sets Q to HIGH. Since the output is wired to $\overline{Q}$, the output will be LOW. The upper comparator uses $\frac{2}{3}V_{cc}$ as a reference. If the threshold voltage falls under $\frac{2}{3}V_{cc}$ then RESET will be asserted, setting Q to LOW. Since the output is connected to $\overline{Q}$, the output will be HIGH.

Figure 2: 555 Timer Monostable Mode Schematic

Monostable Mode of operation is a "one-shot" mode. So on input, monostable mode will make one pulse, and then sleep until another input is asserted. The equation for the length of the pulse is given below

$$t_w = 1.1 \times R_A C$$

Figure 3: 555 Timer Monostable Mode Signals

We see this equation, especially when looking at the signals for the 555 timer on monostable mode, in **Figure 3**. You can see when the input is asserted when it is pulled low, and based on the equation $t_w = 1.1 \times R_A C$ with $R_A = 9.1$ kΩ and $C = 0.01$ μF. This gives us $t_w = 1.1 \times (9.1k\Omega)(0.01\mu F) = (0.1 \times 10^{-4})$s or 0.1ms, which is seen in the waveforms below. You can imagine how the waveforms may differ with different values of R_a and C. Another interesting thing is how the capactior voltage drops down when the input is asserted, and then charges back up according to the differential equation governing its behavior.

Figure 4: 555 Timer Astable Mode Schematic

Astable Mode is an "oscillation" mode, when the input is asserted, the output will pulse repeatedly with a period of $T = t_H + t_L \cong 0.693 \times (R_A + 2R_B) \times C$, where $t_H \cong 0.693 \times (R_A + R_B) \times C$ and $t_L \cong 0.693 \times R_B \times C$. The placement of the resistors and capacitors are shown in **Figure 4**, which is the schematic for low oscillation mode. Where t_H and t_L both denote "time HIGH" and "time LOW". The duty cycle of the circuit is defined to be the amount of time the output is HIGH relative to the period of oscillation. The duty cycle equation is simply given by $\frac{t_H}{t_H+t_L} = \frac{R_A+R_B}{R_A+2R_B}$.

Figure 5: 555 Timer Astable Mode Signals

In **Figure 5**. We see how the capacitor voltage and the output signal changes over time. As we can see, there is a period of oscillation obeying the equations stated above. What is interesting is that as soon as the capacitor charges back up to V_{cc} it then immediately discharges back to GND. This is because the trigger itself is connected to the capacitor.

3 Experimental Procedure

Figure 6: 555 Timer Monostable Experiment Schematic

In order to calculate the amount of time we want the pulse to be on, we need to use the formula $t_w = 1.1 \times R_A C$, since we are targetting a 3 second pulse on, we get the equaton $3 = 1.1 \times R_A C$, simplifying we get that $R_A C = 2.7\overline{27}$, since we are given 100μF capacitors, we can then get that $R_A = \frac{2.7\overline{27}}{100 \times 10^{-6}} \approx 27k\Omega$.

When building the circuit, I started with setting up the power rails on my breadboard, this allows me to make my circuit very organized on my breadboard. Since I connected my power rails, I first connected my power pins (V_{cc} and GND). With those I connected pins that used those signals directly (those being RESET and CONTINUITY). I connected an LED to the OUTPUT pin so I could see the output. After that I went by the schematic. I started with setting up the R_A resistor and the C capacitor as those connections are related to 2 of the pins (those being the DISCHARGE and THRESHOLD pins). I finally connected a push-button to the TRIGGER pin. I made sure to have a pull-up resistor because I do not want my input to be floating as this can cause erratic behavior in my circuit. The reason I use a pull-up is because the OUTPUT is HIGH when INPUT is LOW.

experimental_astable.png

Figure 7: 555 Timer Astable Experiment Schematic

In order to get a 60% duty cycle and a period of 2 seconds. We need to use the equations for t_H and t_L. Since we know that $t_H \cong 0.693 \times (R_A + R_B) \times C = 1.2$ and $t_L \cong 0.693 \times R_B \times C = 0.8$. In both of these equations, we can divide both sides by 0.693 to get $1.7316 = (R_A + R_B) \times C$ and $1.1544 = R_B \times C$. I will just use $C = 100\mu F$ because I have that capacitor available in my kit. This leaves me with $R_B = 11544\Omega$ and $R_A + R_B = 17316\Omega$, using the value we have for R_B, we get that $R_A = 5772\Omega$. Since we do not have these exact values, for R_A I will be using a $5.6k\Omega$ resistor and or R_B I will be using a $12k\Omega$ resistor. This will give us a duty cycle of approximately 60% over a 2 second period. $f = \frac{1}{T} = 0.5$ Hz where $T = t_H + t_L = 2$.

In order to get a 75% duty cycle and a period of 1 second. We need to use the equations for t_H and t_L. Since we know that $t_H \cong 0.693 \times (R_A + R_B) \times C = 0.75$ and $t_L \cong 0.693 \times R_B \times C = 0.25$. I am going to start with making $C = 100\mu F$ because I have that capacitor available in my kit. This gives the equations $0.75 = (0.693 \times 100 \times 10^{-6})(R_A + R_B)$ and $0.25 = (0.693 \times 100 \times 10^{-6})(R_B)$, isolating for R_B in the 2nd equation we get $R_B = 3607\Omega$. Isolating for R_A in the first equation we get $R_A = 7215\Omega$. $f = \frac{1}{T} = 1$ Hz where $T = t_H + t_L = 1$.

Since I already had the 555 Timer monostable cirucit built, I started with whatever I

had there. As you can see, since I was given that circuit to start out with, connecting the rest of the circuit to make it astable circuit. I first took out the input as I no longer needed the input (since the astable circuit will oscillate on its own).

4 Results and Discussion

For the monostable mode, the theoretical result is what I have calculated above. However since we are not using a resistor with a repeating decimal, I will recalculate the theoretical value of the pulse based on the selection of resistors. $t_w = 1.1 \times 27000 \times 100\mu F = 2.97s$.

5 Conclusion and Reference

Here you briefly summarize your findings.
